Acknowledgements

I would like to thank my advisor Dr. Mark Stamp for his guidance and patience. Without his insights, feedbacks, and encouragement, this project would not have been a success. I would also like to express my thanks to the following professors. Dr. Sami Khuri introduced me to hidden Markov models when I first started my graduate studies at San Jose State University. Dr. Kevin Karplus gave me the chance to work with his lab group at UC Santa Cruz, where I learned how to utilize the magnificent power of hidden Markov models to solve practical problems. Dr. Chris Pollett provided me with valuable comments during the formulation of the project topic. Dr. Robert Chun suggested the comparison between our approach and commercial virus scanners.

I would also like to thank my friends and schoolmates for their technical and emotional support. I want to thank Yue Wang for performing the virus scanning, and Peter Hey for repairing my hard disk after it crashed at the most critical moment.

Finally I want to thank my family for their understanding and support throughout my five years of graduate studies. They have shown the greatest care and patience which I truly appreciate.

Abstract

Computer virus writers commonly use metamorphic techniques to produce viruses that change their internal structure on each infection. It is generally believed that these metamorphic viruses are extremely difficult to detect. Metamorphic virus generating kits are readily available, so that little knowledge or skill is required to create these potentially devastating viruses.

In this project, we first analyze four virus creation kits to determine the degree of metamorphism provided by each. We are able to precisely quantify the degree of metamorphism produced by these virus generators. While the best generator, the Next Generation Virus Creation Kit (NGVCK), produces virus variants that differ greatly from one another, the other three generators we examined are much less effective.

We then show that three popular commercial virus scanners cannot detect any of the NGVCK viruses in our test set. We proceed to develop an effective metamorphic virus detection technique based on hidden Markov models (HMM). With this HMM detector, we are able to classify a given program as belonging to a particular virus family or not. Using this approach, we can detect all metamorphic viruses in our test set with extremely high accuracy. We also present a simpler detection method that detects metamorphic viruses with high accuracy.

Our results show that the best available metamorphic generator is effective at morphing viral code and that the resulting morphed viruses are not detectable using popular commercial virus scanning software. Surprisingly, these viruses differ sufficiently from non-viral code so that they are detectable using a similarity technique that we present in this paper. It remains an interesting open question whether metamorphic viral code can be constructed which is undetectable using our techniques.

1. INTRODUCTION

"A computer virus is a program that recursively and explicitly copies a possibly evolved version of itself" [19]. A virus copies itself to a host file or system area. Once it gets control, it multiplies itself to form newer generations. A virus may carry out damaging activities on the host machine such as corrupting or erasing files, overwriting the whole hard disk, or crashing the computer. Some viruses may print text on the screen or simply do nothing. These viruses remain harmless but keep reproducing themselves. In any case, viruses are undesirable for computer users.

Over the past two decades, the number of viruses has been increasing rapidly. We have seen several attacks that caused great disruption to the Internet and brought huge damage to organizations and individuals. For example, in 1999, the infamous Melissa virus infected thousands of computers and caused damage close to \$80 million; while the Code Red worm outbreak in 2001 affected systems running Windows NT and Windows 2000 server and caused damage in excess of \$2 billion [23]. Computer virus attacks will continue to pose a serious security threat to every computer user.

To simplify the virus creation process, virus writers have made virus construction kits readily available on the Internet [22]. This allows people who do not have any expertise in assembly coding to generate their own viruses. Virus writers also recognize that for their viruses to have a chance to escape detection, the viruses created must look different from one another so that a virus signature cannot be easily extracted. Some kits come equipped with the ability to generate automatically morphed variants from a single configuration file. Precisely how effective are these code morphing generators? How different do the morphed variants look? We generated variants of metamorphic viruses using some of these tools and measured the similarity between the morphed variants.

Detecting metamorphic viruses is challenging. The problem with simple signature-based scanning is that even small changes in the viral code may cause a scanner to fail. In

1

addition, the signature database requires constant updates to detect newly morphed variants. We experimented using a single hidden Markov model (HMM) to model an entire virus family. The HMM is then used to determine whether a given program belongs to the virus family that the HMM represents. This approach can be used to distinguish family member viruses from non-member programs.

The challenges with the HMM approach include finding the right balance between sensitivity and specificity, and conforming to the time and space constraints of the computers performing the detection. We evaluated the effectiveness of this approach by its detection rate, the false positive and false negative rates, and the overall accuracy of the classification. We also measured the time to train an HMM and to classify programs. In addition, we scanned our virus data with three commercial virus scanners and compared the results to those of the HMM approach.

This paper is organized as follows. In Section 2, we provide background information on computer viruses and discuss some possible defenses. Section 3 describes our virus similarity test and presents results showing the effectiveness of several metamorphic virus generators. Section 4 details the design, implementation, and experimental results of our HMM detection approach. Section 5 covers how we classify programs using our similarity index and how virus scanners perform on our metamorphic virus data. Section 6 is our conclusion, and finally, we discuss possible extension to the project and future work in Section 7.

2. EVOLUTION OF VIRUSES AND ANTIVIRUS DEFENSE TECHNIQUES

2.1 Virus Obfuscation Techniques

Virus-like programs first appeared on microcomputers in the 1980s [19]. Since then, the battle between virus writers and anti-virus (AV) researchers has never ceased. To challenge virus scanning products, virus writers constantly develop new obfuscation techniques to make virus code more difficult to detect [19]. To escape generic scanning, a

virus can modify its code and alters its appearance on each infection. The techniques that have been employed to achieve this end range from *encryption* to *polymorphic* techniques, to modern *metamorphic* techniques [20].

2.1.1 Encrypted Viruses

The simplest way to change the appearance of a virus is to use encryption. An encrypted virus consists of a small decrypting module (a decryptor) and an encrypted virus body. If a different encryption key is used for each infection, the encrypted virus body will look different. Typically, the encryption method is rather simple, such as xor of the key with each byte of the virus body. Simple xor is very practical because xoring the encrypted code with the key again will give the original code and so a virus can use the same routine for both encryption and decryption.

With encryption, the decryptor remains constant from generation to generation. As a result, detection is possible based on the code pattern of the decryptor. A scanner that cannot decrypt or detect the virus body directly can recognize the decryptor in most cases.

2.1.2 Polymorphic Viruses

To overcome the problem of encryption, namely the fact that the decryptor code is long and unique enough for detection, virus writers started implementing techniques to create mutated decryptors. Polymorphic viruses can change their decryptors in newer generations. They can generate a large number of unique decryptors which use different encryption method to encrypt the virus body. A polymorphic virus thus has no parts that stay constant on each infection.

To detect polymorphic viruses, anti-virus software incorporates a code emulator which emulates the decryption process and dynamically decrypts the encrypted virus body. Because all polymorphic viruses carry a constant virus body, detection is still possible based on the decrypted virus code.

2.1.3 Metamorphic Viruses

To make viruses more resistant to emulation, virus writers developed numerous advanced metamorphic techniques. According to Muttik [14], "Metamorphics are body-polymorphics". A metamorphic virus not only changes it decryptor on each infection but also its virus body. New virus generations look different from one another and they do not decrypt to a constant virus body. A metamorphic virus changes its "shape" but not its behavior. This is illustrated diagrammatically by Szor in [20], and is shown in Figure 1.

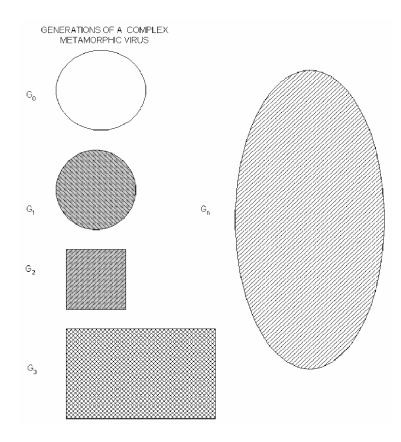

Figure 1 Multiple shapes of a metamorphic virus body [20].

Different techniques have been implemented by virus writers to create mutated virus bodies. One of the simplest techniques employs *register usage exchange*; an example is the W95/Regswap virus [19]. With this technique, a virus uses the same code but different registers in a new generation. Such viruses can usually be detected by a wildcard string [19].

A stronger technique employs *permutation* to reorder a virus's subroutines, as seen in the W32/Ghost virus [19]. With *n* different subroutines, a virus can generate *n*! different virus generations. W32/Ghost has 10 subroutines and so it has 10! = 3,628,800 variations. Even with the high number of subroutine combinations, the virus may still be detected with search strings [19].

More complex metamorphic viruses *insert garbage instructions* between core instructions. Garbage instructions are instructions that are either not executed or have no effect on program outcomes [13]. An example of the former is the nop instruction while "add eax, 0" and "Sub ebx, 0" are sample instructions that do not affect program results. Alternatively, metamorphic viruses *insert jump instructions* into their code to point to the next instruction of the virus code. The Win95/Zperm family of viruses creates new mutations by removal and insertion of jump and garbage instructions as illustrated in Figure 2 [19].

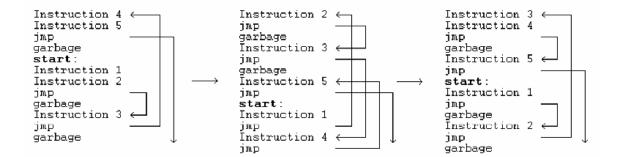

Figure 2 Zperm virus [19].

Another common metamorphic technique is *substitution*, which is the replacement of an instruction or group of instructions with an equivalent instruction or group. For example, a conditional jump (Jcc) can be replaced by JNcc with inverted test condition and swapped branch labels [24]. A "push ebp; mov ebp, esp" sequence can be replaced by "push ebp; push esp; pop ebp" [19]. Sometimes, viruses implement *instruction opcode changes*. For example, to zero out the register eax, we can either xor its content with itself or use sub to achieve the same result. In other words, "xor eax, eax" can be replaced by "sub eax, eax" [19].

Transposition, or rearrangement of instruction order, is another technique used by metamorphic viruses. Instruction reordering is possible if no dependency exists between instructions. Consider the following example from [24]:

op1 [r1] [, r2]

op2 [r3] [, r4] ; here r1 and/or r3 are to be modified

Swapping of the two instructions is allowed if

- 1) r1 not equal to r4; and
- 2) r2 not equal to r3; and
- 3) r1 not equal to r3.

Depending on the implemented techniques, a metamorphic virus can be very complex and very hard to detect even with present day detection techniques. Unlike polymorphic viruses, which decrypt themselves to a constant virus body in memory and provide a complete snapshot of the decrypted virus body during its execution, metamorphic viruses do not become constant anytime anywhere. The detection of metamorphic viruses has been and will likely to continue to be an active research area.

2.1.4 Virus Construction Kits

Viruses are mostly written in assembly language, and not too many people can manage to write complicated and functional assembly code. Some virus-writing groups try to make

the virus creation process quick and easy. They make available many virus construction kits which can generate all kinds of malicious programs like viruses, worms, Trojan horses and logic bombs. Virtually any type of virus can be created – DOS COM / EXE viruses, 16-bit / 32-bit Windows viruses, script viruses, macro viruses, PE viruses, etc [19]. These toolkits are designed to be simple to use and some even come with commercial-grade interactive graphical interfaces. The tools allow anybody, novice or expert, to generate malicious code quickly and easily.

User-friendly as they are, some of these tools are also built with very sophisticated features such as anti-disassembly, anti-debugging, anti-emulation, and anti-behavior blocking. Some kits come equipped with code morphing ability which allows them to produce different-looking viruses. In this sense, the viruses they produce are metamorphic, not just polymorphic. The more highly regarded ones among the 150+ generators available at the VX Heavens [22] include:

- PS-MPC (Phalcon/Skism Mass-Produced Code generator)
- G2 (Second Generation virus generator)
- MPCGEN (Mass Code Generator)
- NGVCK (Next Generation Virus Creation Kit)
- VCL32 (Virus Creation Lab for Win32)

2.2 Antivirus Defense Techniques

As computer viruses evolve and become more complex, antivirus software must become more sophisticated to defend against virus attacks. This section discusses the virus detection techniques that have been deployed over the years. These techniques include:

- 1) pattern-based scanning in first-generation scanners;
- 2) nearly exact and exact identification in second-generation scanners;
- 3) code emulation;
- 4) heuristic analysis to detect new and unknown viruses [19].

2.2.1 First Generation Scanners

The simplest approach to virus detection is string scanning. First generation scanners look for "virus signatures" which are sequences of bytes (strings) extracted from viruses in files or in memory. A good signature for a virus consists of sequences of text strings or byte codes found commonly in the virus but infrequently in benign programs. Usually, a human expert converts the virus binary code into assembly code, looks for sections that signify viral activities and picks the corresponding bytes in the machine code to be the virus signature. More efficient methods use statistical techniques to extract good signatures automatically [8].

Virus signatures are organized into databases. To identify virus infection, virus scanners check specific areas in files or system areas and match them against known signatures in databases. Some simple scanners also support wildcard search strings, such as "??02 33C9 8BD1 419C" where the wildcard is indicated by '?'. Wildcard strings allow skipped bytes and regular expressions and can sometimes be used to detect encrypted or even polymorphic viruses [19]. Using a search string from the common code areas of all known variants of a virus to scan for the virus family is known as generic detection [19]. A generic string typically contains wildcards.

To speed up detection, some scanners search only the start and the end of a file instead of the entire file as early computer viruses are mostly prepending (i.e., attached to the front of the host programs) or appending (i.e., attached to the end of the hosts). Faster scanners look for entry-points, which are common targets of computer viruses, in the headers of executable files.

2.2.2 Second Generation Scanners

Second-generation scanners refine the detection process to detect viruses that evolve to mutate their body. Smart scanning ignores junk instructions like nop and excludes them in virus signatures. Nearly exact identification uses double strings, cryptographic

checksums, or hash functions to achieve higher speed and greater accuracy. Exact identification uses all (as opposed to one in nearly exact identification) constant ranges of the virus bytes to calculate a checksum. Exact identification scanners are usually slower than simple scanners but a well-written one can differentiate virus variants precisely.

2.2.3 Code Emulation

With code emulation, anti-virus software implements a virtual machine to simulate CPU and memory activities. Scanners execute the virus code on the virtual machine rather than on the real processor. Depending on how well the virtual machine mimics system functionalities, few viruses are able to recognize that they are confined and examined in a virtual environment.

Code emulation is a very powerful technique, particularly in dealing with encrypted and polymorphic viruses. Encrypted and polymorphic viruses decrypt themselves in memory. If an emulator is run long enough, the decrypted virus body will eventually present itself to a scanner for detection. The scanner can check its virtual machine's memory when a maximum number of iterations or other stop conditions are met. Alternatively, string scanning can be done periodically every predefined number of iterations. In this way, complete decryption of the virus body is not necessary as long as the decrypted part is long enough for identification. Code emulation can also be applied to metamorphic viruses that use single or multiple encryptions.

Code emulation can become too slow to be useful if the decryption loop is very long, particularly when a virus inserts garbage instructions in its polymorphic decryptor. A new decryption technique uses code optimization to reduce the polymorphic decryptor to its core instruction set. As the emulator iterates through the decryption loop, it removes junk and other instructions that do not change program state. Code optimization speeds up emulation and provides a profile of the decryptor for detection [19].

2.2.4 Heuristic Analysis

Heuristic analysis is used to detect new or unknown viruses. Often times, it is used to detect variants of an existing virus family. Heuristic methods can be static or dynamic. Static heuristics base the analysis on file format and the code structure of virus fragments. Dynamic heuristics use code emulation to simulate the processor and operating system and detect suspicious operations while the virus code is executed on a virtual machine.

Heuristic analysis is prone to false positives. A false positive occurs when a heuristic analyzer incorrectly tags a benign program as viral. These false alarms are not costeffective. Too many false positives destroy users' trust and make a system more vulnerable as users may mistakenly assume a false alarm when it is a real attack.

2.3 Use of Machine Learning Techniques

Various researchers have attempted to use machine learning techniques to perform heuristic analysis on metamorphic viruses. This section covers the result and potential of some of the techniques, which include:

- 1) data mining methods
- 2) neural networks
- 3) hidden Markov models.

2.3.1 Data Mining Approach

Data mining methods are often used to detect patterns in a large set of data. These patterns are then used to identify future instances in a similar type of data. Schultz et al. experimented with a number of data mining techniques to identify new malicious binaries [17]. They used three learning algorithms to train a set of classifiers on some publiclyavailable malicious and benign executables. They compared their algorithms to a traditional signature-based method and reported a higher detection rate for each of their algorithms. However, their algorithms also resulted in higher false positive rates when compared to signature-based method. The key to any data mining framework is the extraction of features, which are properties extracted from examples in the dataset. Schultz et al. extracted some static properties of the binaries as features. These include system resource information (the list of DLLs, the list of DLL function calls, and the number of different function calls within each DLL) obtained from the program header, and consecutive printable characters found in the files. The most informative feature they used was byte sequences, which were short sequences of machine code instructions generated by the hexdump tool.

The features were used in three different training algorithms. There was an inductive rule-based learner that generated Boolean rules to learn what a malicious executable was; a probabilistic method that applied Bayes rule to compute the likelihood of a particular program being malicious, given its set of features; and a multi-classifier system that combined the output of other classifiers to give the most likely prediction.

2.3.2 Neural Networks

Researchers at IBM implemented a neural network for heuristic detection of boot sector viruses [21]. The features they used were short byte strings, called trigrams, which appear frequently in viral boot sectors but not in clean boot sectors. They extracted about 50 features from a corpus of training data, which consisted of both viral and legitimate boot sectors. Each sample in the dataset was then represented by a Boolean vector indicating the presence or absence of these features.

The network was single-layered with no hidden units. It was trained using classic backpropagation technique. One common problem with neural network is overfitting, which occurs when a network is trained to identify the training set but fails to generalize to unseen instances. To eliminate this problem, multiple networks were trained using different features and a voting scheme was used to determine the final prediction.

The neural network was able to identify 80-85% of viral boot sectors in the validation set with a false positive rate of less than 1%. The neural network classifier has been incorporated into the IBM AntiVirus software which has identified about 75% of new boot sector viruses since it was released [21]. A similar technique was later applied by Arnold and Tesauro to successfully detect Win32 viruses [1]. From [21], we can conclude that neural networks are very effective in detecting viruses closely related to those in the training set. They can also identify new families of viruses containing similar features as the training samples.

2.3.3 Hidden Markov Models

Hidden Markov models (HMMs) are well suited for statistical pattern analysis. Since their initial application to speech recognition problems in the early 1970's [15], HMMs have been applied to many other areas including biological sequence analysis [10].

An HMM is a state machine where the transitions between states have fixed probabilities. Each state in an HMM is associated with a probability distribution for observing a set of observation symbols. We can "train" an HMM to represent a set of data, which is usually in the form of observation sequences. The states in the trained HMM then represent the features of the input data, while the transition and the observation probabilities represent the statistical properties of these features. Given any observation sequence, we can match it against a trained HMM to determine the probability of seeing such a sequence. The probability will be high if the sequence is "similar" to the training sequences.

In protein modeling, HMMs are used to model a given family of proteins [11]. The states correspond to the sequence of positions in space while the observations correspond to the probability distribution of the 20 amino acids that can occur in each position. A model for a protein family assigns high probabilities to sequences belonging to that family. A trained HMM can then be used to discriminate family members from non-members.

Metamorphic viruses form families of viruses. Even though members in the same family mutate and change their appearances, some similarities must exist for the variants to maintain the same functionality. Detecting virus variants thus reduces to finding ways to detect these similarities. Hidden Markov models provide a means to describe sequence variations statistically. We propose to use HMMs similar to those used in protein sequence analysis to model virus families. In virus modeling, the states correspond to the features of the virus code, while the observations are instructions or opcodes making up the program. A trained model should then be able to assign high probabilities to and thus identify viruses belonging to the same family as the viruses in the training set.

3. SIMILARITIES BETWEEN VARIANTS OF METAMORPHIC VIRUSES

It has generally been agreed that for a virus to escape detection, metamorphism is the best approach. Different generations of a virus must look different to avoid detection by signature-based scanning. Some of the virus creation toolkits that we mentioned in Section 2.1.4, including G2 (Second Generation virus generator) and NGVCK (Next Generation Virus Creation Kit), come with the ability to generate morphed versions of the same virus, even from identical configurations. In this section, we look at how "effective" these generators are, or how "different" are the variants generated by the same engine. We use a similarity index and also a graphical representation to display the similarity between two assembly programs.

3.1 Method to Compare Two Pieces of Code

To compare two pieces of code, we employed the method developed by Mishra in [12]. His method compares two assembly programs and assigns a quantitative score to represent the percentage of similarity between the two programs.

Mishra's method is outlined below and is illustrated graphically in Figure 3.

 Given two assembly programs X, and Y for which we want to measure their similarity, we extract the sequence of opcodes for each of the programs, excluding comments, blank lines, labels, and other directives. The result is two opcode sequences of length n, and m, where n and m are the numbers of opcodes in programs X and Y, respectively. Each opcode is assigned an opcode number: the first opcode is 1, the second is 2, and so on.

- 2) We compare the two opcode sequences by considering all subsequences of three consecutive opcodes from each sequence. We count as a match any case where all three opcodes are the same in any order, and we mark on a graph the coordinate (x, y) of the match where x is the opcode number of the first opcode of the three-opcode subsequence in program X and y is the opcode number of the opcode subsequence in program Y.
- 3) After comparing the entire opcode sequences and marking all the match coordinates, we obtain a graph plotted on a grid of dimension n × m. Opcode numbers of program X are represented on the x-axis and those of program Y are represented on the y-axis. To remove noise and random matches, we only retain those line segments of length greater than the threshold value five.
- 4) Since we are performing a sequential match between the two opcode sequences, identical segments of opcodes will form line segments parallel to the main diagonal (if n = m, the main diagonal is simply the 45 degree line). If a line segment falls right on the diagonal, the matching opcodes are at identical locations on the two opcode sequences. A line off the diagonal indicates that the matching opcodes appear at different locations in the two files.
- 5) For each axis, we count the number of opcodes that are covered by one or more of the matching line segments. This number is divided by the respective total number of opcodes (n for program X and m for program Y) to give the percentage of opcodes that match some opcodes in the other program. The similarity score for the two programs is the average of these two percentages.

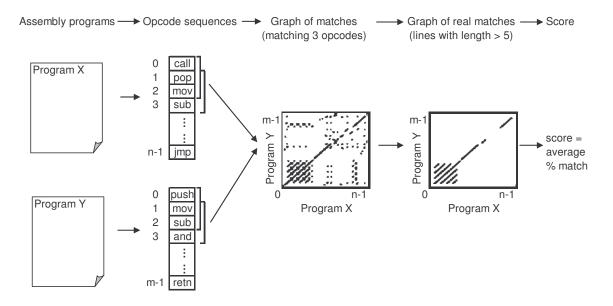

Figure 3 Process of finding the similarity between two assembly programs.

3.2 Test Data

We analyzed 45 viruses generated by four virus generators that we downloaded from VX Heavens [22]. We also compared some randomly chosen utility programs from the Cygwin DLL [4] to see how viruses differ from "normal" executable files. The programs that we analyzed include:

- 20 viruses generated by NGVCK (Next Generation Virus Creation Kit) version
 0.30 released in June 2001;
- 10 viruses generated by G2 (Second Generation virus generator) version 0.70a released in January 1993;
- 10 viruses generated by VCL32 (Virus Creation Lab for Win32) released in February 2004;
- 5 viruses generated by MPCGEN (Mass Code Generator) version 1.0 released in 1993;
- 20 randomly chosen utility executables from the Cygwin DLL version 1.5.19.

The virus variants were named after their generators as follows:

- the 20 viruses generated by NGVCK were named NGVCK0 to NGVCK19;
- the 10 generated by G2 were named G0 to G9;
- the 10 generated by VCL32 were named VCL0 to VCL9;
- the 5 generated by MPCGEN were named MPC0 to MPC4.

The 20 random utilities files were named R0 to R19.

The viruses created by the virus generators were in assembly source code. To make virus executable files, we assembled them with the Borland Turbo Assembler TASM 5.0. The generated executables were then disassembled by the IDA Pro Disassembler [6] version 4.6.0. All the disassembling used the same default settings. The cygwin utilities were also disassembled by IDA Pro. The sequence of process is summarized as:

We added the prefix "IDA_" to the respective file names to denote that the files were disassembled ASM files created by IDA Pro and to distinguish them from the original ASM files. For example, the file disassembled from R0.EXE was named IDA_R0.ASM.

We compared the disassembled assembly (ASM) files instead of the original assembly codes generated by the virus generators. We believed by assembling and disassembling with the same tools using the same settings, we can eliminate some differences due to different coding style of the different virus writers. The standardized disassembling process makes for more accurate comparison when we compare the viruses generated by different generators, or when we compare viruses with random "normal" programs. It makes the similarity measure better reflect the effectiveness of the metamorphism employed. The process also simulates a more realistic scenario because when detecting viruses in real environment, what we have available are virus executables. That is, disassembling and analyzing the resultant assembly files is what we need to do in practice.

3.3 Test Results

For each of the virus generator, we compared each of the viruses to all the other viruses generated by the same generator, to see how "effective" the generator is in terms of generating different-looking virus variants. For each pair of virus variants under comparison, we computed their similarity score using the method described above in Section 3.1. Comparisons were also made between the random normal files. The raw similarity scores of all the comparisons are given in Table A-1 to Table A-5 in Appendix A. Figure 4 below is a scatter plot showing the similarity scores of the 190 pair-wise comparisons among the 20 NGVCK viruses and the 190 pair-wise comparisons among the 20 NGVCK viruses and the 190 pair-wise comparisons are lower than those between normal files.

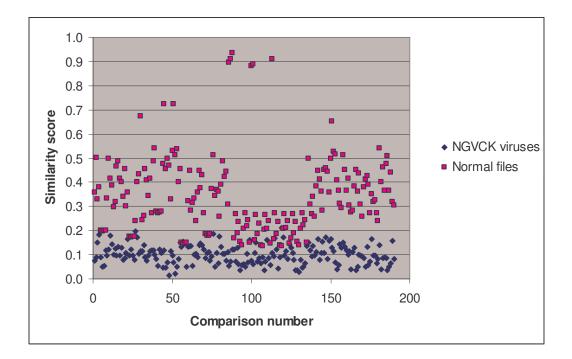

Figure 4 Scatter plot showing similarity scores between NGVCK virus variants and between normal files.

The minimum, maximum, and average scores of each generator and the normal files are summarized below in Table 1.

Minimum, maximum, and average similarity scores					
	NGVCK	G2	VCL32	MPCGEN	Normal
min	0.01493	0.62845	0.34376	0.44964	0.13603
max	0.21018	0.84864	0.92907	0.96568	0.93395
average	0.10087	0.74491	0.60631	0.62704	0.34689

Table 1 Minimum, maximum, and average similarity scores between virus variants generated by thegenerators and between normal files.

Comparing the four generators, NGVCK generates viruses of the lowest similarities, which range from 1.5% to 21.0% with an average of about 10.0%. The other generators are not as effective at generating different-looking viruses. The similarities between two variants of the same virus range from 34.4% to 96.6%, and the average scores of G2, VCL32, and MPCGEN are 74.5%, 60.6%, and 62.7%, respectively. Compare to random normal files, which have an average similarity of 34.7%, we can see that the viruses that NGVCK generates are substantially different from one another, while the virus variants generated by the other generators are more similar to one another than normal files.

These comparison results are represented graphically by the bubble graph in Figure 5. Here the minimum score is shown along the x-axis; the maximum score is shown along the y-axis; and the size of the bubble represents the average similarity. Under this representation, an effective generator would have a bubble that is very close to the origin and also has a very small size, since effectively morphed variants of a virus should have low minimum, low maximum and low average similarities.

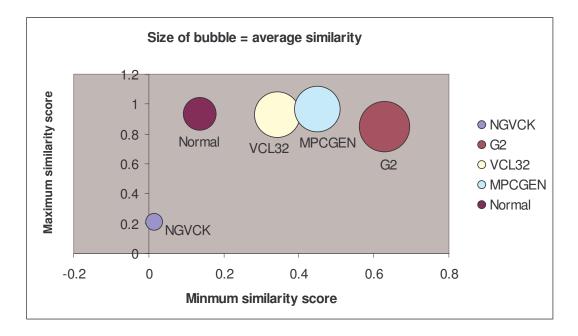

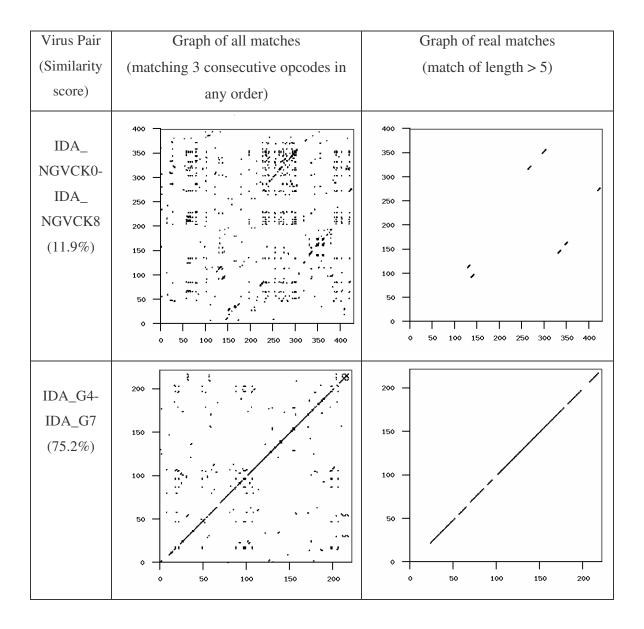

Figure 5 Bubble graph showing minimum, maximum, and average similarity between virus variants generated by each generator and between normal files.

As is shown in the graph, NGVCK clearly outperforms the other generators in terms of generating different-looking viruses. VCL32 and MPCGEN have similar morphing ability as their variants have comparable minimum, maximum, and average similarities. G2 viruses have a higher average similarity, as is represented by the bigger bubble size, although the maximum similarity of the variants is lower than that of VCL32 and MPCGEN viruses. Normal files have similarities higher than NGVCK viruses but lower than virus variants produced by generators G2, VCL32, and MPCGEN.

The following table shows the similarity graphs of some of the virus pairs. For each generator, we chose a representative pair which has a similarity score close to the average similarity score, to illustrate how a typical virus pair differ from each other. The first column gives the virus names with their similarity score in parenthesis. The second column shows the graphs of all matches, as defined in Section 3.1 above. The third

column shows the graphs of real matches after noise and random matches have been removed. The pairs selected and their scores are:

- IDA_NGVCK0 against IDA_NGVCK8, similarity = 11.9%
- IDA_G4 against IDA_G7, similarity = 75.2%
- IDA_VCL0 against IDA_VCL9, similarity = 60.2%
- IDA_MPC1 against IDA_MPC3, similarity = 58.0%
- normal files IDA_R0 and IDA_R1, similarity = 35.7%.

 Table 2 Similarity graphs of four selected virus pairs and one normal file pair.

If we take a closer look at the graphs for the pair of G2 viruses and the pair of VCL32 viruses, we can see that the real matches are almost all along the diagonal. This indicates that virus variants of the same virus have identical opcodes at identical positions. This is obviously not very effective metamorphism. On the other hand, the matches between the MPCGEN virus pair are off the diagonal, which shows that identical opcodes appear in different positions of the two virus variants. From this evidence, we can say that MPCGEN has a greater morphing ability than the other two generators. NGVCK is the most effective in the sense that the match segments are very short and that they are way off the diagonal. Even if we look at the pair that has the highest similarity (IDA_NGVCK7 and IDA_NGVCK14, similarity = 21.0%), the match segments are still short and off the diagonal. The two similarity graphs of this pair are shown below.

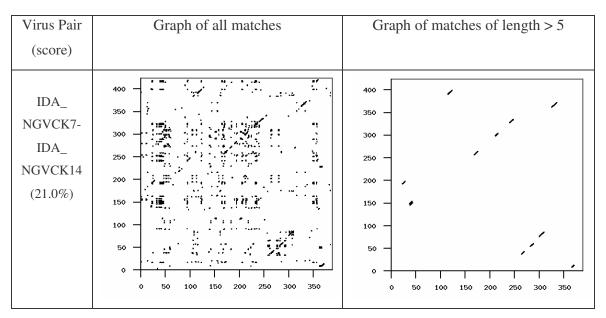

Table 3 Similarity graphs of the NGVCK virus pair that has the highest similarity.

As the Next Generation Virus Creation Kit (NGVCK) was found to be the most effective based on our similarity measure, we were interested to know how the viruses it generates differ from the viruses generated by the other generators. We compared the first 10 NGVCK viruses (IDA_NGVCK0 to IDA_NGVCK9) against each of the following viruses:

- IDA_G0 to IDA_G9 (10 files);
- IDA_VCL0 to IDA_VCL9 (10 files);
- IDA_MPC0 to IDA_MPC4 (5 files).

Our result shows that the NGVCK viruses are very different from the other viruses. Each of the comparisons against the G2 viruses and against the MPCGEN viruses produces a similarity score of 0. Of the 100 comparisons against the VCL32 viruses, 57 comparisons have similarity score of 0, while the other 43 comparisons that show some similarity have scores range from 1.2% to 5.5%, with an average of 2.4%. These scores are very low compared to the similarity scores we have seen so far. The scores of the 43 pairs that have similarity greater than zero are shown in Table A-6 in Appendix A. The similarity score of 5.5%, is shown in Table 4.

Virus Pair	Graph of all matches	Graph of matches of length > 5
(score)		
IDA_ NGVCK0- IDA_VCL4 (5.5%)	$200 - \frac{1000}{100} + \frac{1000}{100} $	200 - 150 - 100 - 150 200 250 300 350 400

Table 4 Similarity graphs showing similarity between IDA_NGVCK0 and IDA_VCL4.

We also compared the NGVCK viruses to the normal files. All the 20 NGVCK viruses were compared to the 20 normal files. All but 8 of the 400 comparisons again show no similarity. The eight pairs that show some similarity have very low score of 0.98% to 1.12%. The scores are shown below in Table 5.

Similarity score	es between			
IDA_NGVCK2	IDA_R11	0.01001	min	0.00981
IDA_NGVCK5	IDA_R10	0.01123	max	0.01123
IDA_NGVCK6	IDA_R16	0.01021	average	0.01031
IDA_NGVCK7	IDA_R5	0.01007		
IDA_NGVCK7	IDA_R6	0.00981		
IDA_NGVCK7	IDA_R7	0.00990		
IDA_NGVCK7	IDA_R8	0.01010		
IDA_NGVCK7	IDA_R13	0.01115		

Table 5 The eight pairs of NGVCK viruses and normal files that have non-zero similarity scores.

Using the same representation scheme, where we show the minimum similarity score along the x-axis, the maximum score along the y-axis, and the average similarity by the size of a bubble, we display the comparison results using the bubble graph in Figure 6. The bubble labeled "NGVCK vs NGVCK" represents the result of comparing NGVCK viruses against NGVCK viruses. The graph illustrates that NGVCK viruses not only have low similarities among themselves, they show even lower similarities when compared to other viruses or normal programs. We conclude that NGVCK viruses are very different from other viruses and normal utility programs.

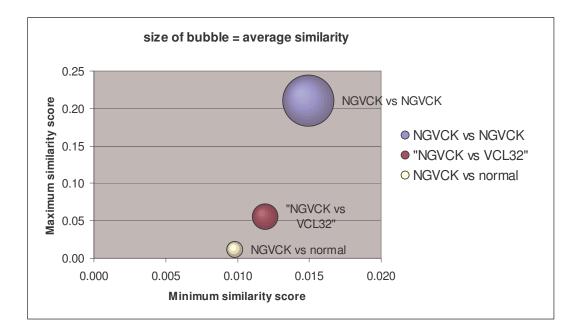

Figure 6 Minimum, maximum, and average similarities between NGVCK virus variants, between NGVCK viruses and VCL32 viruses, and between NGVCK viruses and normal files.

4. HIDDEN MARKOV MODELS TO DETECT VIRUSES IN SAME FAMILY

In this project, we developed a system to train multiple hidden Markov models (HMMs) on a set of metamorphic virus variants. The trained models were tested for their ability to detect morphed variants of the same virus. The effectiveness of the HMM approach is determined by the detection rate, the number of false positives and false negatives, and the overall accuracy.

4.1 Theory and Algorithms for Hidden Markov Models

A hidden Markov model is a statistical model that describes a series of observations generated by a stochastic process, or Markov process. A Markov process is a sequence of states, where the progression to the next state depends solely on the present state but not on the past states. The Markov process in an HMM is "hidden"; what we can see is the sequence of observations associated with the states. Our goal is to make use of the observable information to gain insight into various aspects of the underlying Markov process [18].

We illustrate these concepts by an example taken from [18]. Suppose we want to know the average annual temperature of a particular location over a preceding period of several consecutive years and suppose that there is no recording of past temperature of any form for this location. Since there is no way to know the year-to-year temperature directly, we look for evidence to predict the temperature indirectly.

For simplicity, we consider only two possible annual temperatures: "hot" (H) or "cold" (C). Suppose we know that the probability of a hot year followed by another hot year is 0.7 and that of a cold year followed by another cold year is 0.6. This information can be represented by the matrix:

$$\begin{array}{ccc}
H & C \\
H \begin{bmatrix} 0.7 & 0.3 \\
0.4 & 0.6 \end{bmatrix}
\end{array}$$

Now assume research result tells us that the tree ring size of a certain kind of tree, whether it is small (S), medium (M), or large (L), is related to the annual temperature as:

	S	M	L
Η	0.1	0.4	0.5
С	0.7	0.2	0.5 0.1

meaning that in a hot year, the probability of a tree having a small, medium, or a large tree ring is 0.1, 0.4 and 0.5 respectively. If we observe the tree ring sizes for such a tree, we can use this information to deduce the possible annual temperatures over the years of interest.

In this example, the temperatures (H and C) are the states and the transition of temperature from year to year defines the Markov process. Tree ring sizes (S, M, L) are the observable outcomes and the probabilities of seeing the different tree ring sizes at

each temperature represent the probability distribution of the observation symbols at each state. The actual states are "hidden" since we cannot directly observe the temperatures. What we can see are the observations (tree ring sizes) and these are related to the states statistically.

Suppose we represent the observation symbols *S*, *M*, *L* by 0, 1, 2 respectively and suppose that a particular four-year series of observed tree ring sizes is given by the observation sequence O = (0, 1, 0, 2). We might want to find the most likely state sequence of the Markov process that generates the observation sequence. In other words, we may want to determine the most likely annual temperatures (*H* or *C*) over this series of four years from our observation of the tree ring sizes.

4.1.1 Notation

Let

T = the length of the observed sequence N = the number of states in the model M = the number of distinct observation symbols $O = \text{the observation sequence} = \{O_0, O_1, \dots, O_{T-1}\}$ $Q = \text{the set of states of the Markov process} = \{q_0, q_1, \dots, q_{N-1}\}$ $V = \text{the set of observation symbols} = \{0, 1, \dots, M-1\}$ A = the state transition probability distributions B = the observation probability distributions $\pi = \text{the initial state distribution}$ $\lambda = (A, B, \pi) = \text{the HMM defined by its parameter } A, B, \text{ and } \pi.$

Figure 7 shows a generic HMM. The state and observation at time *t* are represented by X_t and O_t respectively. The Markov process, which is hidden behind the dashed line, is determined by the initial state X_0 and the *A* matrix. What we can observe are the observations O_t , which are related to the states of the Markov process by the *B* matrix.

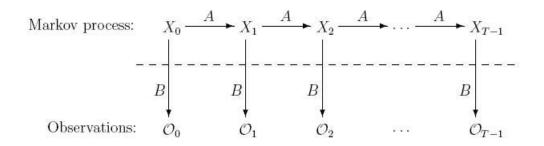

Figure 7 A generic hidden Markov model [18].

For our temperature example, the state transition matrix A is defined by the probabilities of temperature transitions from year to year; the observation matrix B is defined by the probabilities of observing the tree ring sizes. That is,

$$A = \begin{bmatrix} 0.7 & 0.3 \\ 0.4 & 0.6 \end{bmatrix}, \text{ and}$$
$$B = \begin{bmatrix} 0.1 & 0.4 & 0.5 \\ 0.7 & 0.2 & 0.1 \end{bmatrix}$$

which are the same matrices given previously.

The matrix $A = \{a_{ij}\}$ is $N \times N$ with

$$a_{ij} = P(q_i \text{ at } t+1 \mid q_i \text{ at } t)$$

representing the probability of making a transition from state q_i at time *t* to state q_j at time *t*+1.

The matrix $B = \{b_i(k)\}$ is $N \times M$ with

 $b_j(k) = P(\text{observation } k \text{ at } t \mid \text{state } q_j \text{ at } t)$

representing the probability of observing symbol k at time t given we are in state q_j at time t.

The matrix $\pi = \{\pi_i\}$ is $1 \times M$ with

$$\pi_i = P(q_i \text{ at } t = 0)$$

representing the probability of being initially in state q_i at time 0. We assume for the temperature example that $\pi = \begin{bmatrix} 0.6 & 0.4 \end{bmatrix}$.

The matrices *A*, *B*, and π make up the parameters of an HMM. Note that *A*, *B*, π are row stochastic, i.e., each row of these matrices represents a probability distribution and therefore must sum to 1 [18].

For a generic state sequence $X = (x_0, x_1, x_2, x_3)$ of length four, with corresponding observations $O = (O_0, O_1, O_2, O_3)$. The probability of the state sequence *X* is given by

$$P(X \mid \lambda) = \pi_{x0} b_{x0}(O_0) a_{x0, x1} b_{x1}(O_1) a_{x1, x2} b_{x2}(O_2) a_{x2, x3} b_{x3}(O_3)$$

where π_{x_0} is the probability of starting in state x_0 , $b_{x_0}(O_0)$ is the probability of observing O_0 at x_0 and a_{x_0, x_1} is the probability of transiting from state x_0 to state x_1 . This easily generalizes to a sequence of any length.

In our temperature example, with observation sequence O = (0, 1, 0, 2), we can compute the probability of this observation sequence having been generated by each four-state sequence. For example, the probability that observation O was generated by the state sequence *HHCC* is

$$P(HHCC) = 0.6(0.1)(0.7)(0.4)(0.3)(0.7)(0.6)(0.1) = 0.000212$$

In the same manner, we can compute the probability of each of the possible state sequences of length four, given the fixed observation sequence *O*. These probabilities are listed in Table 6. We will have some more to say about these probabilities when we discuss the HMM algorithms.

state sequence	probability			
HHHH	0.000412			
HHHC	0.000035

max probability	0.002822			

Table 6 Probabilities of observing O = (0, 1, 0, 2) for all possible 4-state sequences.

In general, the three problems that we are interested in solving with an HMM are [18]:

- Given the model $\lambda = (A, B, \pi)$ and an observation sequence *O*, find $P(O \mid \lambda)$. That is, find the likelihood of observing the sequence *O* given the model.
- Given λ = (A, B, π) and an observation sequence O, find an optimal state sequence that could have generated O. (This is what we wanted to do in the temperature example above.) Note that "optimal" here has at least two interpretations. We can reasonably define optimal as:
 - the state sequence with the highest probability from among all possible state sequences; or
 - 2) the state sequence that maximizes the expected number of correct states.
- Given an observation sequence *O*, the number of states *N*, and the number of symbols *M*, find the model parameters, i.e., the probabilities in the *A*, *B*, and π matrices, that maximize the probability of observing *O*. This is a discrete hill climb on the (*A*, *B*, π)-parameter space. In other words, we re-adjust the model parameters to best fit the observations.

4.1.2 Algorithms

There exist efficient algorithms to solve the three problems listed above. A thorough review of these algorithms can be found in [15] and [7]. In this section, we look at some of these algorithms, which include:

- the *Forward-Backward* algorithm for calculating the probability of being in a state q_i at time t given an observation sequence O;
- the *Viterbi* algorithm for finding the most likely state sequence given *O*; and
- the *Baum-Welch* algorithm for iteratively re-estimating the parameters A, B, π .

4.1.2.1 Finding the likelihood of an observation sequence: the Forward algorithm In the previous section, we saw that the probability of an observation sequence $O = (O_0, O_1, ..., O_{T-1})$ generated by a particular state sequence $X = (x_0, x_1, ..., x_{T-1})$ given a model λ is given by

$$P(O, X \mid \lambda) = \pi_{x_0} b_{x_0}(O_0) a_{x_0, x_1} b_{x_1}(O_1) a_{x_1, x_2} \dots a_{x_{T-2}, x_{T-1}} b_{x_{T-1}}(O_{T-1})$$

To find the probability of observing the sequence *O*, we generate all possible state sequences X_i of length *T* and sum over the probabilities $P(O, X_i | \lambda)$.

$$P(O \mid \lambda) = \sum_{X_i} P(O, X_i \mid \lambda)$$

= $\sum_{X_i} \pi_{x_0} b_{x_0}(O_0) a_{x_0, x_1} b_{x_1}(O_1) a_{x_1, x_2} \dots a_{x_{T-2}, x_{T-1}} b_{x_{T-1}}(O_{T-1})$

Going back to our temperature example, the probability of observing tree ring sizes O = (0, 1, 0, 2) given our model is equal to the sum of all the probabilities listed in Table 6, which is 0.009629.

The probability $P(O \mid \lambda)$ tells us how well the observation sequence *O* matches the HMM λ . If λ has *N* states and *O* has length *T*, then there are N^T possible state sequences.

Finding the probability $P(O, X_i | \lambda)$ for one of the state sequence X_i requires about 2T multiplications and so a direct computation of the summation requires about $2TN^T$ computations, which is infeasible even for small HMMs.

Instead of generating all possible state sequences, we use the Forward algorithm (sometimes called the α -pass) to compute this probability efficiently. For t = 0, 1, ..., T - 1 and i = 0, 1, ..., N - 1, define a forward variable

$$\alpha_t(i) = P(O_0, O_1, ..., O_t, x_t = q_i | \lambda)$$

which denotes the probability of observing the partial sequence $(O_0, O_1, ..., O_t)$ up to time *t* and being in state q_i at time *t*. The forward variables can be found recursively using the following recurrence relation:

Step 1 Initialization:

$$\alpha_0(i) = \pi_i b_i(O_0), \quad \text{for } i = 0, 1, \dots, N-1$$

Step 2 Induction:

$$\alpha_t(i) = \left[\sum_{j=0}^{N-1} \alpha_{t-1}(j) a_{ji}\right] b_i(O_t), \quad \text{for } t = 1, 2, \dots, T-1 \text{ and } i = 0, 1, \dots, N-1.$$

Figure 8 illustrates the inductive process of finding $\alpha_t(i)$ using the variables $\alpha_{t-1}(j)$.

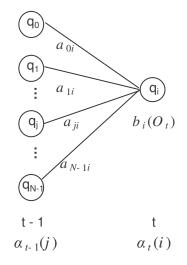

Figure 8 Inductive process of finding $\alpha_t(i)$ from variables $\alpha_{t-1}(j)$.

The probability of observing the sequence *O* given the model λ , $P(O \mid \lambda)$, can then be calculated as

$$P(O \mid \lambda) = \sum_{i=0}^{N-1} P(O_0, O_1, ..., O_{T_i} x_T = q_i \mid \lambda)$$
$$= \sum_{i=0}^{N-1} \alpha_{T-1}(i).$$

The recursive computation requires N^2T multiplications, which is much better than $2TN^T$ for the naive approach.

4.1.2.2 Finding the most likely state sequence: the Viterbi algorithm

Given an observation sequence $O = (O_0, O_1, ..., O_{T-1})$ and an HMM λ , the Viterbi algorithm finds a highest scoring overall path X^* that maximizes the probability $P(O, X | \lambda)$. We can determine the state sequence that is mostly likely to occur given the observation sequence.

For t = 0, 1, ..., T - 1 and i = 0, 1, ..., N - 1, let $\delta_t(i)$ denote the probability of the most probable state path $(x_0, x_1, ..., x_t)$ that generates the partial sequence $(O_0, O_1, ..., O_t)$ up to time *t* and ending in state q_i ,

$$\delta_t(i) = \max_{x_0 \dots x_{t-1}} P(O_0, O_1, \dots, O_{t_i}, x_0, x_1, \dots, x_{t-1}, x_t = q_i \mid \lambda)$$

The $\delta_t(i)$ values can be found recursively as follows:

Step 1 Initialization:

$$\delta_0(i) = \pi_i b_i(O_0), \quad \text{for } i = 0, 1, \dots, N-1$$

Step 2 Induction:

$$\delta_t(i) = \max_{0 \le j \le N-1} [\delta_{t-1}(j)a_{ji}] b_i(O_t), \quad \text{for } t = 1, 2, \dots, T-1 \text{ and } i = 0, 1, \dots, N-1.$$

At each successive *t*, the algorithm gives the probability of the best path ending at each of the states i = 0, 1, ..., N - 1. Consequently, the probability of the most likely state sequence for the observation sequence *O* is

$$P^* = \max_{0 \le i \le N-1} \left[\delta_{T-1}(i) \right]$$

The Viterbi algorithm is similar to the Forward algorithm, except that maximizations replace the summations in the recursive calculations. Notice that the $\delta_t(i)$ values are probabilities values only. To actually find the state sequence X^* , we can use backpointers at each step to keep track of the best states chosen along the path. The path can then be extracted by backtracking from the highest-scoring final state.

For our temperature example given at the beginning of Section 4.1, the mostly likely state sequence is *CCCH*, having the highest probability of 0.002822 as shown in Table 6.

4.1.2.3 Finding the optimal model parameters: the Baum-Welch algorithm

One of the most useful features of an HMM is that we can efficiently re-adjust the model parameters to best fit the observations. Given the matrix dimensions N and M, we can iteratively re-estimate the elements of A, B, and π so that the probability of observing an observation sequence O is maximized.

Before we discuss the re-estimation algorithm, let us first take a look at the Backward algorithm, or β -pass, which is analogous to the α -pass given above. For t = 0, 1, ..., T - 1 and i = 0, 1, ..., N - 1, define the backward variable

$$\beta_t(i) = P(O_{t+1}, O_{t+2}, ..., O_{T-1} \mid x_t = q_i, \lambda)$$

which denotes the probability of observing the partial sequence $(O_{t+1}, O_{t+2}, ..., O_{T-1})$ given we are in state q_i at time t.

 $\beta_t(i)$ measures the probability after time *t* and can be obtained recursively starting at the end of the sequence:

Step 1 Initialization:

$$\beta_{\text{T-1}}(i) = 1$$
, for $i = 0, 1, ..., N - 1$

Step 2 Induction:

$$\beta_t(i) = \sum_{j=0}^{N-1} a_{ij} b_j(O_{t+1}) \beta_{t+1}(j), \text{ for } t = T-2, T-1, \dots, 0 \text{ and } i = 0, 1, \dots, N-1.$$

Figure 9 illustrates the recursive process.

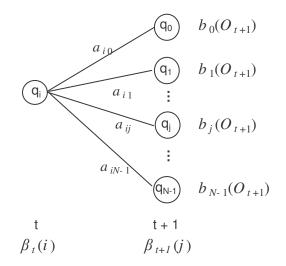

Figure 9 Inductive process of finding $\beta_t(i)$ from variables $\beta_{t+1}(j)$.

The Backward algorithm also gives us the probability of observing the sequence *O* given the model λ , or $P(O \mid \lambda)$, which should be the same number produced by the Forward algorithm:

$$P(O \mid \lambda) = \sum_{i=0}^{N-1} \pi_i b_i(O_0) \beta_0(i) \,.$$

Now, define the probability of being in state q_i at time *t* given the observation sequence *O* and the model λ , for t = 0, 1, ..., T - 2 and i = 0, 1, ..., N - 1, as

$$\gamma_t(i) = P(x_t = q_i \mid O, \lambda).$$

This probability can be obtained from the forward-backward variables as

$$\gamma_{t}(i) = \frac{\alpha_{t}(i)\beta_{t}(i)}{P(O \mid \lambda)}$$
$$= \frac{\alpha_{t}(i)\beta_{t}(i)}{\sum_{i=0}^{N-1}\alpha_{t}(i)\beta_{t}(i)}$$

since $\alpha_t(i)$ accounts for the observations up to time *t* and $\beta_t(i)$ accounts for the observations after time *t* given we are in state q_i at time t. The denominator $P(O \mid \lambda) = \sum_{i=0}^{N-1} \alpha_t(i) \beta_t(i)$ is the normalization factor, which makes $\gamma_t(i)$ a probability distribution and sum to 1.

Next, define the joint probability of being in state q_i at time t and transiting to state q_j at time t + 1, for t = 0, 1, ..., T - 2 and $i, j \in \{0, 1, ..., N - 1\}$, as

$$\gamma_t(i,j) = P(x_t = q_i, x_{t+1} = q_j \mid O, \lambda).$$

This probability can be written in terms of α , β , A, and B as

$$\gamma_t(i,j) = \frac{\alpha_t(i)a_{ij}b_j(O_{t+1})\beta_{t+1}(j)}{P(O \mid \lambda)}.$$

The relationship among these probabilities is illustrated graphically in Figure 10.

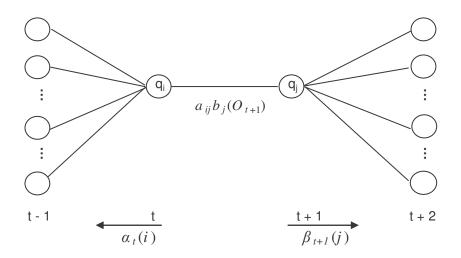

Figure 10 Variables for the computation of the joint probability $\gamma_t(i, j)$.

The $\gamma_t(i)$ and $\gamma_t(i, j)$ are related by

$$\gamma_t(i) = \sum_{j=0}^{N-1} \gamma_t(i, j)$$

 $\gamma_t(i)$ gives us the probability of being in state q_i at time t. If we sum the probability over all possible T, we get the expected number of transitions from state q_i to any state. $\gamma_t(i, j)$ gives us the joint probability of being in state q_i at time t and in state q_j at time t + 1. The summation of $\gamma_t(i, j)$ over T thus gives the expected number of transitions from state q_i to state q_j . In other words,

 $\sum_{t=0}^{T-2} \gamma_t(i) = \text{the expected number of transitions from state } q_i \text{ to any state, and}$ $\sum_{t=0}^{T-2} \gamma_t(i, j) = \text{the expected number of transitions from state } q_i \text{ to state } q_j.$

We can now re-estimate the parameters of $\lambda = (A, B, \pi)$ using the following formulae: For i = 0, 1, ..., N - 1,

$$\pi_i = \gamma_0(i)$$

= probability of being in state q_i at t = 0.

For
$$i = 0, 1, ..., N - 1$$
 and $j = 0, 1, ..., N - 1$,

$$\overline{a}_{ij} = \sum_{t=0}^{T-2} \gamma_t(i, j) / \sum_{t=0}^{T-2} \gamma_t(i)$$
$$= \frac{\text{Expected number of transitions from } q_i \text{ to } q_j}{\text{Expected number of transitions out of } q_i}$$

For
$$j = 0, 1, ..., N - 1$$
 and $k = 0, 1, ..., M - 1$,

$$\overline{b}_{j}(k) = \sum_{\substack{t=0\\O_{t}=k}}^{T-2} \gamma_{t}(j) / \sum_{t=0}^{T-2} \gamma_{t}(j)$$

 $\frac{\text{Expected number of times the model is in state } q_j \text{ with observation } k}{\text{Expected number of times the model is in state } q_j}$

We re-estimate λ iteratively until $P(O \mid \lambda)$ does not increase (or the increase is less than a predefined threshold) or until the maximum number of iterations is reached. The complete Baum-Welch expectation-maximization (EM) algorithm can be summarized as:

- 1) Initialize $\lambda = (A, B, \pi)$ with a best guess. If no prior information is available, choose random $\pi_i \approx 1/N$, $a_{ij} \approx 1/N$, and $b_j(k) \approx 1/M$.
- 2) Calculate $\alpha_t(i)$, $\beta_t(i)$, $\gamma_t(i)$ and $\gamma_t(i, j)$.
- 3) Re-estimate the model $\overline{\lambda} = (\overline{A}, \overline{B}, \overline{\pi})$, and calculate $P(O \mid \overline{\lambda})$.
- 4) Stop if $P(O \mid \overline{\lambda}) P(O \mid \lambda)$ is less than the predefined threshold or the maximum number of iterations is reached; otherwise set $\lambda = \overline{\lambda}$ and goto (2).

4.1.2.4 Posterior state probabilities

The Viterbi algorithm given in Section 4.1.2.2 finds the most probable state path through the model. But as we mentioned in Section 4.1.1, there is a second interpretation as to what constitutes an "optimal" state sequence. Instead of finding the highest scoring overall path, as is done by the Viterbi algorithm, we may want to find the most probable state for each specific observation O_t in the observation sequence $O = (O_0, O_1, ..., O_{T-1})$. More generally, we may want to find the probability that observation O_t is generated by state q_i given the sequence O, i.e., $P(x_t = q_i | O, \lambda)$. This is called the posterior probability of state q_i at time t.

This posterior probability is exactly the $\gamma_t(i)$ variable defined above in Section 4.1.2.3, which is given by

$$P(x_t = q_i \mid O, \lambda) = \frac{\alpha_t(i)\beta_t(i)}{P(O \mid \lambda)}.$$

Hence, the optimal path that finds the most probable state for each position is obtained by finding, for each t = 0, 1, ..., T - 1, the state q_i for which $\gamma_t(i)$ is maximum.

This state sequence is not necessarily the same as the highest scoring sequence found by the Viterbi algorithm. We may be more interested in this sequence that maximizes all posterior probabilities when there are many different paths that have probabilities very close to the most probable one, or when we want to know only the state assignment at a particular point *t* rather than the complete path. It is possible that this state sequence may not be particularly likely as a path through the HMM. Sometimes it is not even a legitimate path when some of the transitions between states are not allowed.

4.1.3 Implementation Issues: Underflow and Scaling

The HMM computations discussed in Section 4.1.2 require repeated multiplications of the transition and observation probability values. One major challenge in the implementation is to deal with these small products which tend to zero exponentially as T

increases and can easily cause underflow if care is not taken. To solve this problem, we can scale the forward and backward variables while maintaining the validity of the reestimation formulae.

The scaled version of the Forward algorithm normalizes each $\alpha_t(i)$ by dividing by the sum (over *j*) of all $\alpha_t(j)$ for each value *t*, or observation O_t . Let $\tilde{\alpha}_t(i)$ denotes the forward probability that is scaled up to t - 1 but not scaled for *t* yet; $\hat{\alpha}_t(i)$ denotes the scaled probability; and $\alpha_t(i)$ denotes the non-scaled probability as given in the original forward algorithm. The scaling coefficient c_t at each time *t* is defined by

$$c_t = \frac{1}{\sum_{j=0}^{N-1} \widetilde{\alpha}_t(j)},$$

where $c_0 = \frac{1}{\sum_{j=0}^{N-1} \alpha_0(j)}$ and $\hat{\alpha}_0(i) = c_0 \alpha_0(i)$ for i = 0, 1, ..., N-1 when t = 0.

Then for each t = 1, 2, ..., T - 1, calculate

$$\widetilde{\alpha}_{t}(i) = \sum_{j=0}^{N-1} \widehat{\alpha}_{t-1}(j) a_{ji} b_{i}(O_{t}) \text{ and}$$
$$\widehat{\alpha}_{t}(i) = c_{t} \widetilde{\alpha}_{t}(i) \qquad \text{for } i = 0, 1, \dots, N-1$$

The scaled probabilities are now normalized so that $\sum_{i=0}^{N-1} \hat{\alpha}_i(i) = 1$. Also, it can be proven

by induction that

$$\hat{\alpha}_t(i) = c_t \tilde{\alpha}_t(i)$$
$$= c_0 c_1 \dots c_t \alpha_t(i).$$

Combining these two properties and setting t = T - 1, we have

$$1 = \sum_{j=0}^{N-1} \hat{\alpha}_{T-1}(j)$$

$$\Leftrightarrow \quad 1 = c_0 c_1 \dots c_{T-1} \sum_{j=0}^{N-1} \alpha_{T-1}(j)$$

$$\Leftrightarrow \quad 1 = c_0 c_1 \dots c_{T-1} P(O \mid \lambda)$$

$$\Leftrightarrow \quad P(O \mid \lambda) = \frac{1}{\prod_{j=0}^{T-1} c_j}.$$

To avoid underflow, we compute the log likelihood, $\log[P(O \mid \lambda)]$, instead of $P(O \mid \lambda)$:

$$\begin{split} \log[P(O \mid \lambda)] &= \log \frac{1}{\prod_{j=0}^{T-1} c_j} \\ &= -\sum_{j=0}^{T-1} \log c_j \,. \end{split}$$

The same scale factor c_t is used for $\beta_t(i)$ so that $\hat{\beta}_t(i) = c_t \beta_t(i)$. The computations of $\gamma_t(i)$ and $\gamma_t(i, j)$ use the same formulae as given in Section 4.1.2.3 substituting $\hat{\alpha}_t(i)$ and $\hat{\beta}_t(i)$ for $\alpha_t(i)$ and $\beta_t(i)$. These values are then used to re-estimate the model parameters *A*, *B*, and π .

The implementation of the Viterbi algorithm can also result in underflow. This is avoided by taking logarithms. The underflow-resistant Viterbi algorithm is defined as: Step 1 Initialization:

$$\hat{\delta}_0(i) = \log[\pi_i b_i(O_0)], \quad \text{for } i = 0, 1, ..., N-1$$

Step 2 Induction:

$$\hat{\delta}_{t}(i) = \max_{0 \le j \le N-1} \{ \hat{\delta}_{t-1}(j) + \log[a_{ji}] + \log[b_{i}(O_{t})] \},$$

for $t = 1, 2, ..., T-1$ and $i = 0, 1, ..., N-1$.

The optimal log probability is given by

$$\log P^* = \max_{0 \le i \le N-1} [\hat{\delta}_{T-1}(i)]$$

and as before back-pointers can be used to keep track of the optimal path.

4.2 HMM for Computer Virus Detection

Given a set of metamorphic virus variants, our goal is to train one or more hidden Markov models (HMMs) to represent the statistical properties of the virus family so that we can later use a trained model to determine whether a given program is similar to the viruses in the training set.

We trained our models based on the assembly opcode sequences of the virus files. For viruses originally generated in assembly source format, we first compiled the assembly source into executables using TASM 5.0. We then disassembled the executables using IDA Pro with identical default settings. We trained our models on the IDA-generated files rather than the original assembly source from the virus generators. We believed this makes our method more realistic. Disassembling executables is typically part of the virus analysis process. This virus pre-processing procedure is the same as the one we used in the virus similarity test in Section 3 and is summarized again below:

Virus Assembly Source Virus Executables Virus Executables Disassembled Virus ASM Files

There are generally two approaches to training an HMM when there are multiple observation sequences. We can either concatenate the sequences and make them into one long observation sequence; or train the HMM with each sequence separately and average the parameters from the different trainings [7]. We chose the former approach in our training process. With the set of pre-processed virus ASM files, we extracted the assembly opcode sequences, concatenated them into one long sequence of opcodes and used it to train our HMMs. A trained model maximizes the probability of observing the training sequence. By calculating the probability of observing any given sequence in the HMM and comparing it to the probability of observing the training sequence, we know how well the given sequence matches the training sequence, or how "similar" the given sequence is to the training sequence. When trained with multiple sequences, the resulting HMM represents the "average" behavior, or the behavior of all the sequences in the form of a statistical profile. We can represent a whole virus family, as opposed to individual viruses, with a single HMM. The probability of any sequence in the HMM then tells us how likely it is that the given sequence belongs to the same virus family.

One extremely useful aspect of an HMM is that it tells us something about the training sequence without any requirement that we interpret the observations or underlying features. Without specific knowledge of the features of the metamorphic viruses, we trained our HMMs using different number of states and examined the resulting probabilities to deduce what features the states represent. The number of states *N* that we tested were N = 2, 3, 4, 5, and 6. To remain flexible, we did not define a fixed set of opcodes as observable symbols. Instead, we set *M* equal to the total number of distinct opcodes actually seen in the training sequences for each model. The number of observation symbols thus varied from model to model. With our data, *M* was typically around 70 to 80. The viruses we trained on were about 350 to 450 opcodes long, with an average length of 416 opcodes. Concatenating 160 virus opcodes to train a model made the length of the observed training sequence *T* in the range of 66,000 to 67,000. The average *T* for the models we trained was 66,650.

Our HMM implementation used the scaled version of the Forward and the Backward algorithm as discussed in Section 4.1.3. To avoid underflow, we computed the log likelihood, instead of the raw probability, of observing the training sequence in the model at each step of the iterative training process. Re-estimation stopped when the log

likelihood of the training sequence converged or a maximum of 800 iterations had been reached.

4.3 Training and Testing

We collected a large number of metamorphic virus variants generated by a virus creation kit to form a *data set*. Training and testing was done using standard cross-validation methodology [9]. With five-fold cross validation, we divide the data set into five equal-sized subsets. Each time when we train a model, we choose one of the subsets as the test set and train the model using data from the other four subsets. Because data from the test set is not used during training, we can use it to evaluate the performance of the model over unseen instances of the same virus. Repeating this process five times, choosing a different subset as the test set each time, we can get five different models from the same set of data.

Viruses generated by a code morphing generator form a virus family, as they are morphed versions of the same virus and have the same behavior. We consider viruses generated by different generators as belonging to different families. After training, an HMM should assign high probabilities to files similar to the training viruses and low probabilities to all other files, whether they are "normal" benign programs or viruses from different families. We made a *comparison set* which consisted of normal executables of sizes comparable to the executables of the viruses in the data set (about 8 KB). The comparison set also contained viruses created by generators other than the one used to generate the data set.

With a trained model, we computed the log likelihood of the virus variants in the test set and the programs in the comparison set. Log likelihood is strongly length dependent, since it is a sum of log transition probabilities and log observation probabilities. A longer sequence will naturally have more transitions and more observations and thus a greater log likelihood, independent of how similar it is to the training sequences. Because the

44

sequences in the comparison set may have lengths different from the sequences in the training and test set, we divided the log likelihood of a sequence by the sequence length (which is the number of opcodes) to obtain the *log likelihood per opcode (LLPO)*, which adjusts for the length difference. This LLPO is the score of the sequence.

Comparing the scores of the files in the test set, which are viruses in the same family as the files used for training, and the scores of the files in the comparison set, which are random non-viral programs or viruses in other families, there should be a separation of scores between the two sets as the trained model should assign higher probabilities and thus higher LLPO to files in the same virus family. From these empirical scores, we determined a threshold, above which we will consider a file as belonging to the same family as the viruses in the training set. To classify whether a program is in the same virus family as the training data, we compute its score and compare it to the threshold.

The training and classifying process is summarized below and is illustrated graphically in Figure 11.

Training:

- Given a data set consisting of different variants of a metamorphic virus, pick one subset as the test set and use the remaining four subsets for training.
- 2) Train HMM λ for sequences in the training set until the log likelihood of the training sequence converges or a maximum number of iterations is reached.
- 3) Compute the score, i.e., the log likelihood per opcode (LLPO), of viruses in the test set and other files in the comparison set.
- Determine a cutpoint (threshold) score above which a file is classified as a member virus. The threshold separates virus family members from non-members.
- 5) Repeat from (1), choosing a different subset as the test set, until all five subsets have been chosen.

Classifying:

1) To determine whether any program is part of the virus family, score and compare its LLPO to the model thresholds.

Training:

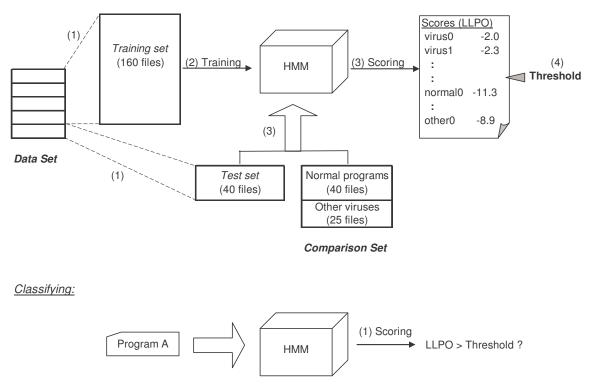

Figure 11 Training and classifying process.

The HMM algorithms were implemented in C and compiled with Visual C++ 2005 Express Edition. We wrote some Ruby scripts using Ruby 1.8.4 on Windows [16] to perform the cross-validation. All trainings are carried out on a Pentium M 1.4 GHz machine running Windows XP Home Edition with 768 MB of RAM.

4.4 Data Used

Our data set consisted of 200 viruses generated by the Next Generation Virus Creation Kit (NGVCK), which was shown to be the most effective of the four virus generators we tested in Section 3. With five-fold cross validation, the number of viruses in each test set was 40 and the number of sequences used for training was 160 for each model.

After training, we compared the scores of the 40 family viruses in the test set to the scores of the programs in the comparison set. There were 65 files in the comparison set consisting of both benign and viral programs. These included:

- 40 random executable files chosen from the Cygwin DLL (version 1.5.19) to represent "normal" benign programs. The first 20 were the same ones that we used in our similarity test in Section 3;
- 25 viruses generated by the three generators G2, MPCGEN, and VCL32. They
 were the same programs that we tested for similarity in Section 3.

All these programs were unique and there were no duplicates. Training and testing used files disassembled by IDA Pro (version 4.6.0) [6]. The four generators are downloadable from [22] while the Cygwin DLL is available at [4].

The IDA-preprocessed files were named as follows:

- the 200 viruses in the data set were named IDA_N0 to IDA_N199 (N for NGVCK);
- the 40 "normal" files in the comparison set were named IDA_R0 to IDA_R39 (R for random);
- the 25 "other" viruses in the comparison set were named IDA_V0 to IDA_V24 (V for viruses).

The 200 viruses in the data set were divided into five subsets according to virus number:

- Test set 0: IDA_N0 to IDA_N39;
- Test set 1: IDA_N40 to IDA_N79;
- Test set 2: IDA_N80 to IDA_N119;
- Test set 3: IDA_N120 to IDA_N159;
- Test set 4: IDA_N160 to IDA_N199.

4.5 Experimental Results

For each N = 2, 3, 4, 5, and 6 hidden states, training and testing was run as described above and five models were obtained for each *N* giving a total of 25 models.

4.5.1 Separation of Scores

We first examined how the HMMs separate viruses in the test set from normal benign programs. We called viruses in the test set "family viruses" as they were generated by the same virus generator (NGVCK) that created the viruses used for training. This is in contrast with "non-family viruses" in the comparison set which were viruses generated by generators other than NGVCK. The random utility files in the comparison set were called "normal files".

Of the 25 models, 23 models were able to make a clear separation of scores between family viruses and normal files, meaning the scores (in log likelihood per opcode, LLPO) of the 40 family viruses were always higher than the scores of the 40 normal files. Table 7 shows the scores of test set 0 using the model with N = 2 states. With this model, all family viruses in the test set scored -4.43 or higher while all normal files scored -8.07 to as low as -169.19. Figure 12 is a scatter plot showing all these scores. We can see that all the normal file scores are below the family virus scores.

Test set 0, N = 2

Table 7 LLPO scores of the 40 family viruses in test set 0 and the 40 normal files using the model with N = 2.

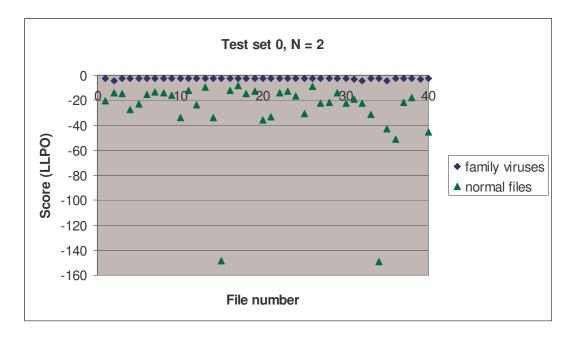

Figure 12 Difference in scores between family viruses and normal files.

The kind of clear separation that we saw in the previous model was typical for most models. This is illustrated in Table 8 where for each model we compare the minimum score of the family viruses to the maximum score of the normal files. The minimum is higher than the maximum in most cases. Two exceptions occurred with test set 1, where one family virus (IDA_N51) had a score that fell within the score range of the random files, for the two models with N = 2 and 3. Other than these two cases, the models made a clear distinction of scores between family viruses and normal programs. We can easily distinguish a virus from a normal program by their scores in the HMMs.

		min score of family viruses	max score of normal files
	N = 2	-4.4349	-8.0663
	N = 3	-5.8575	-8.9071

	N = 6	-4.1822	-7.4662

Table 8 Minimum score of the 40 family viruses and maximum score of the 40 normal programsassigned by each model.

Next, we examined how the HMMs perform when we included the non-family viruses in the comparison set. Seven of the models made a complete separation of scores between viruses in the test set and files in the comparison set. That is, the LLPO of the family viruses were all higher than those of the normal files as well as the non-family viruses. For the other models, we find some overlapping of scores where some non-family viruses have scores higher than some of the family viruses.

Figure 13 shows the result of the model with three states (i.e., N = 3) using test set 0. For this case, the score distinction between family viruses and non-family viruses is not as clear. Some non-family viruses in the comparison set have scores very close to or higher

than the family viruses. In fact, these non-family viruses are the VCL32 viruses which we showed in Section 3 that they possess some similarities to NGVCK viruses. Our HMMs separated these viruses, which have some similarities to the viruses the HMMs represent, from the other non-family viruses, which have zero similarity to the NGVCK viruses. As is shown in Figure 13, the scores for the VCL32 viruses are much higher than the scores for the other non-family viruses.

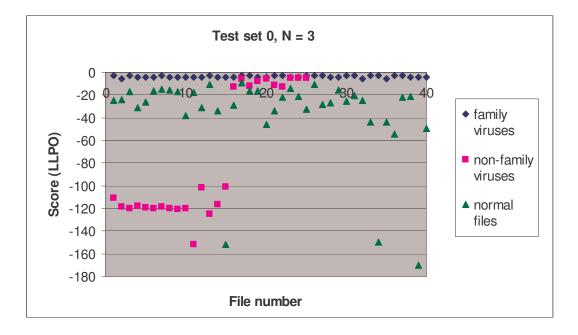

Figure 13 Log likelihood per opcode (LLPO) of family viruses, non-family viruses and normal files.

The result illustrated in Figure 13 is common to most models. In fact, if we look at the graph for each of the test sets for each N, the score distribution is very similar. If a file has a low score in one model, it always has a low score in all other models, although the scores are not always identical. We have included more of these graphs in Appendix B. Table B-1 shows the models trained with N = 3 states and Table B-2 shows the models with N = 5 states. The shapes of the curves are very similar in every graph. The raw scores of all the test runs are listed in Table B-3 in Appendix B. Our HMMs showed consistent performance over the test data, regardless of the number of hidden states: all

normal benign programs were distinguishable by their scores; non-family viruses showing no similarity to the viruses represented by the HMMs had very low scores; and non-family viruses having some similarities to the family viruses had scores closer to the family viruses.

4.5.2 Threshold and False Predictions

Next we counted the number of *false positives* and *false negatives* associated with each model. A false positive occurs when a program not belonging to the virus family represented by an HMM is classified by the HMM as being a member virus. A false negative occurs when a member virus is misclassified as being a non-member. Analogously, true positives are family viruses correctly classified as members; while true negatives are programs not belonging to the virus family correctly classified as non-members.

Recall that a trained HMM classifies a program by comparing its log likelihood per opcode (LLPO) to the threshold LLPO. The choice of threshold value therefore affects the classification and thus the amount of false positives and false negatives a model produces. If we choose a higher threshold, fewer programs would score higher than the threshold and there would be fewer false positives. This, however, is usually accompanied by more false negatives as more member viruses may have scores lower than the threshold. Depending on the desired tradeoff, we could select the threshold accordingly.

Note that the HMMs made a separation of scores between family viruses and normal programs (except for the one virus IDA_N51). If we reasonably choose a threshold that is lower than all family virus scores and higher than all normal file scores, no normal files will become false positives and no family viruses will become false negatives. (And for the two models where IDA_N51 had a score lower than some normal file, there will be one false positive out of the 40 family viruses.) The issue of false positives, false

negatives and their tradeoff arises only when we take into account the non-family viruses, because their score range interleaves with the family virus score range. In other words, false positives would mainly come from the non-family viruses, particularly the VCL32 viruses as they are the only viruses that scored close to the family viruses. False negatives occur when we adjust the threshold to reduce the number of misclassified VCL32 viruses.

We determined the amount of false positives and false negatives that came with different threshold values. Figure 14 illustrates the tradeoff between the two when the threshold changes from -3.5 to -2.5, for the model with N = 2 hidden states using test set 4. The actual counts are shown in Table 9.

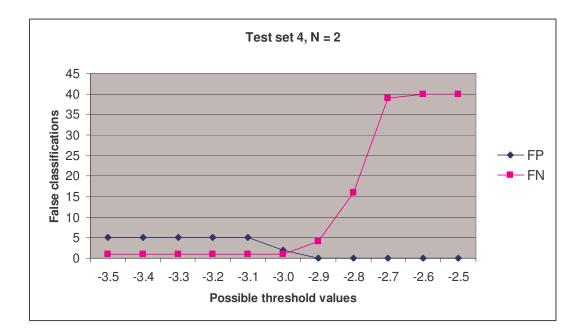

Figure 14 Tradeoff between false positives (FP) and false negatives (FN) with changing threshold values.

Threshold	-3.5	-3.4	-3.3	-3.2	-3.1	-3.0	-2.9	-2.8	-2.7	-2.6	-2.5
FP	5	5	5	5	5	2	0	0	0	0	0
FN	1	1	1	1	1	1	4	16	39	40	40

Table 9 False positive (FP) and false negative (FN) counts for threshold ranging from -3.5 to -2.5. This model used test set 4 and N = 2.

4.5.3 Detection Rate, False Positive Rate, and Overall Accuracy

Besides the raw false positive and false negative counts, we calculated three other performance measures based on these counts: *detection rate*, *false positive rate*, and *overall accuracy*. The detection rate tells us the sensitivity of the model and is defined as the number of member viruses that are caught by an HMM divided by the total number of member viruses in the test set (40 in our experiments). The false positive rate is related to the specificity of the model and is defined as the number of false positives divided by the total number of non-member programs in the comparison set (65 in our test runs). Overall accuracy is defined as the number of true predictions (positives and negatives) divided by the total number of member and non-member programs (105 in our tests). The three measures are related to true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN) as follows:

- Detection rate $= \frac{\text{TP}}{\text{TP} + \text{FN}}$, as TP + FN equals total number of member viruses tested;
- *False positive rate* = $\frac{FP}{FP + TN}$, as FP + TN equals total number of non-member programs tested;

• Overall accuracy =
$$\frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}}$$

The detection rate, false positive rate, and overall accuracy of the test run above are shown in Figure 15. We plotted the rates from threshold -4.5 to -2.5. The three rates are again functions of the threshold. At a threshold value of -3.0, the detection rate and

overall accuracy are 97.5% and 97.1% respectively while the false positive rate is 3.1%. If we increase the threshold to -2.9, the false positive rate would be 0% but both detection rate and accuracy would drop to 90% and 96.2%, respectively.

Test set 4, N = 2

Figure 15 Comparison of false positive rate, detection rate and overall accuracy.

Suppose we want to limit the false negative rate to 10%. In other words, we want to have a detection rate of 90% or more. The threshold values that would produce the desired detection performance are listed in Table 10. The value for each model is the largest threshold LLPO that can still maintain a false negative rate of 10%. If we choose a threshold lower than the listed value, it is possible to achieve a higher detection rate, although it is likely that the false positive rate will also increase. The false positive rates for all the models, at the respective threshold values, fall within 0% to 7.7%. Even the

detection rate and overall accuracy of all models are quite similar, the models with three states (i.e., N = 3) produced 0% false positives with all the five test sets. In this sense, models with three states have slightly better performance than the other models.

Detection	n rate >= 90%	threshold	FP	FN	detect rate	FP rate	accuracy
	test set 0	-3.0	2	3	0.925	0.031	0.952

	test set 4	-2.6	0	4	0.900	0.000	0.962

Table 10 Threshold LLPO with detection rate of 90% or more for each model.

Finally, we pick the value -4.5, which is the lowest threshold in the analysis above, and see how the performance measures would change with this lower threshold value. Table 11 shows the false positive count, false negative count, detection rate, false positive rate and overall accuracy when we set the cutpoint at -4.5 for all the models. Compared to the previous table, the detection rates as well as the false positive rates indeed have increased for most models. We see that 17 of the models have detection rate reaching 100% and 10

models have 0% false positive rate. Although the performance of all the models is quite similar, models with two states (N = 2) do have slightly higher false positive rates and lower accuracy. All models with three states (N = 3) maintain their false positive rates at 0% but their detection rates are lower than the other models. We conclude there is not a significant difference in performance between models with three or more states.

 Table 11 False positive count, false negative count, detection rate, false positive rate and overall accuracy when threshold is set at -4.5 for all models.

4.5.4 Run Time of the Training and Classifying Process

Training an HMM is an iterative process. As discussed in Section 4.1.2 where the HMM algorithms were presented, each iteration consists of an α -pass, a β -pass, the computation

of the γ values, the re-estimation of the model parameters, and the calculation of the log likelihood of the training sequence [18]. Each of these steps, except the calculation of log likelihood, requires computations in the order of N^2T , where N is the number of states in the model and T is the length of the training sequence. Thus each iteration requires $O(N^2T)$ time and the total run time is also proportional to the number of iterations taken.

We recorded the training time of the models and the result is shown in Figure 16. We timed the trainings twice setting the maximum number of iterations to 500 and 800 respectively. T was around 66,500 for all models. With 500 iterations, training time ranged from 5 minutes to 23 minutes. With 800 iterations, training time ranged from 9 minutes to 38 minutes depending on the number of states N.

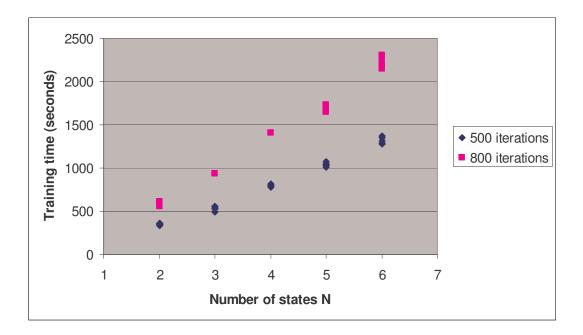

Figure 16 Training time of the 25 models using 500 iterations and 800 iterations respectively.

Classifying a program requires the computation of its log likelihood per opcode (LLPO) in a model. We compute this score by running the α -pass, which is an O(N^2T) inductive process. Since the score is found in only one α -pass, the scoring of a program in a HMM

is relative fast, compared to the training of a model. We recorded the time it took our models to score each of the virus files and the normal programs and plotted the result in Figure 17. Our models can score files of any length and the length T (in number of opcodes) of our data ranged from 100 to 1400. The time to score a program range from 0.008 milliseconds to 0.4 milliseconds, depending on the number of states N of the model and the number of opcodes T in the program.

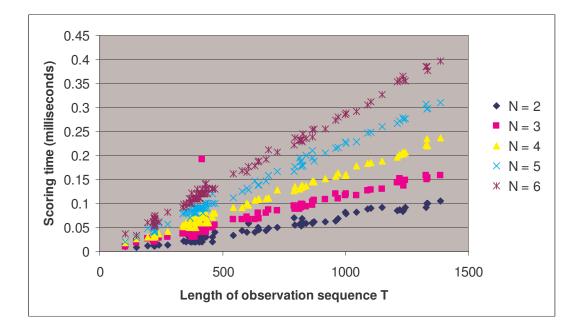

Figure 17 Scoring time as a function of observation sequence length T and number of states N.

The algorithms for training were implemented in C and the scoring routine was written in Ruby [16]. Each training and each scoring was let to run by itself on a Pentium M 1.4 GHz machine running Windows XP Home Edition with 768 MB of RAM.

4.6 The Trained Models

We trained the hidden Markov models (HMMs) using different number of states without knowing how to interpret the observations and what features the viruses contain. Theoretically, the final converged probabilities in the HMM matrices (i.e., A, B, and π),

particularly the *B* matrix which contains the observation probabilities of the observable symbols (i.e., opcodes) at each state, should help us reveal the significant features of the viruses on which the HMMs are trained. We examined the final parameters of our HMMs to infer what the features might be. We found that the opcodes can readily be grouped under the states. More than half of the opcodes are seen in one state only, meaning that each of these opcodes has an observation probability of zero in all but one state. For each of the other opcodes which has non-zero observation probabilities in more than one state, we can still easily find the state that it belongs because one of the observation probabilities usually stands out. In other words, the opcodes form a partition into states. By examining the grouping of opcodes, it is possible to discover what each state represents. Table 12 is the transpose of the converged *B* matrix for the model with N = 3 states using test set 0 (i.e., trained on test set 1 to 4). We sorted the opcodes by their probabilities in state 0.

Table 12 The final B matrix transpose for model with N = 3 using test set 0.

In Figure 18, we graphed the probability distributions of the opcodes in Table 12. Here we can easily see that the peaks for each state appear at different locations. Certain opcodes are predominately seen in a particular state only. Opcodes that are mostly seen only in state 0 include pop, jz, retn, jnz, and call. Those that are mostly seen in state 1

include push, popa, and cmp. Opcodes that have high probabilities only in state 2 include add and move.

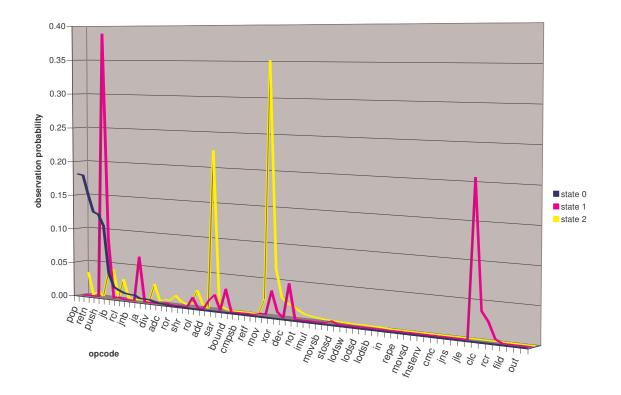

Figure 18 Probability distributions of observation symbols for each state in the model with N = 3 using test set 0.

To show the relative probabilities of each opcode being seen in each of the three states, we normalize, for each opcode, its probabilities in state 0, state 1, and state 2 so that the three observation probabilities sum to 1. The relative probabilities tell us in which state each opcode appear mostly. Again as we can see in Figure 19, most opcodes appear in one state only.

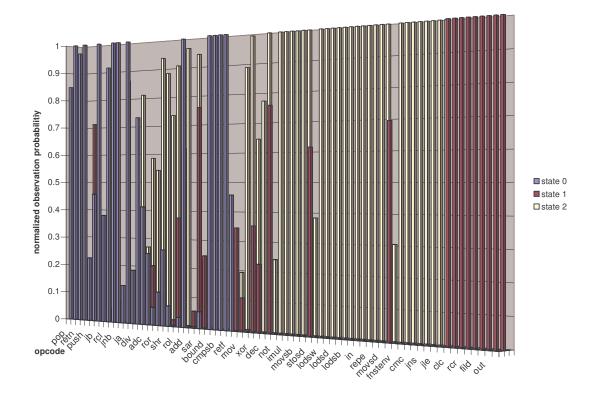

Figure 19 Probabilities of each opcode in state 0, state 1, and state 2 normalized to show the composition of states for each opcode.

The groupings of opcodes are not always the same in all our models. But that the opcodes always form a partition remain the same for all models. We included some more converged matrices *A*, *B*, and π in Appendix C.

5. DETECTION WITH SIMILARITY INDEX AND COMMERCIAL SCANNERS

5.1 Classifying by Similarity Index

In the similarity tests described in Section 3, we found that viruses generated by the Next Generation Virus Creation Kit (NGVCK) are only about 10% similar among themselves, on average. They share even lower similarities when compared to normal programs (0 to 1.1%), and when compared to other viruses not in the same family (0 to 5.5%). Since

these NGVCK-viruses are so different from other programs, benign or viral, it is possible to distinguish them by using similarity index alone.

This straight-forward approach would work as follows. To classify whether a program belongs to the NGVCK virus family, compare the program to any randomly chosen NGVCK virus. If it has no similarity to the NGVCK virus, it is classified as non-family (i.e. not belonging to the NGVCK family). Otherwise, we compare some more NGVCK viruses to the chosen NGVCK virus to determine a threshold. If the similarity score of the program with the original chosen NGVCK virus is higher than the threshold value, it is classified as a family virus.

We used this approach to classify the 40 family viruses IDA_N0 to IDA_N39, the 40 normal files, and the 25 non-family viruses generated for the tests in Section 4. We ran two tests where we compared the 105 files to IDA_N146 and IDA_N101 respectively. The similarity scores for the test using IDA_N146 for comparison are shown in Table 13.

Comparing	IDA_N146	i to:				Threshold determination:

Table 13 Similarity scores between IDA_N146 and other programs including NGVCK viruses, non-NGVCK viruses, and normal programs.

The column on the right in Table 13 shows the minimum score and the maximum score when IDA_N146 was compared to some other NGVCK viruses. Suppose we simply used the minimum score of 0.0349 as the threshold, we were able to correctly classify all the

105 files. All family viruses had scores greater than 0.0349 while all other programs scored lower than the threshold value. In other words, the detection rate was 100% and false positive rate was 0% in this test.

The test using IDA_N101 for comparison also achieved a 100% detection rate and a 0% false positive rate when we used the same criteria to set the threshold. The scores for this test are shown in Table D-1 in Appendix D. This straight-forward approach, which uses similarity index for classification, worked remarkably well in our two tests. Accuracy was 100% and there were no false positives or false negatives in either case.

5.2 Detection by Virus Scanners

Finally, we tested whether the NGVCK viruses can be detected by commercial virus scanners. We stored 37 virus executables in a disk folder and scanned the folder using three different scanners:

- eTrust version 7.0.405 [5],
- avast antivirus version 4.7 [2], and
- AVG Anti-Virus version 7.1 [3].

The 37 viruses were all used in our HMM tests in Section 4. The executables included:

- 10 EXE files from the NGVCK (Next Generation Virus Creation Kit) viruses;
- 10 COM files from the G2 (Second Generation virus generator) viruses;
- 10 EXE files from the VCL32 (Virus Creation Lab for Win32) viruses; and
- 7 COM files from the MPCGEN (Mass Code Generator) viruses, which were in fact PS-MPC (Phalcom/Skism Mass-Produced Code Generator) viruses as MPCGEN runs PS-MPC within its code after it generates some random configuration files (cfg files).

eTrust and avast detected 17 viruses, which are the G2 viruses and the MPCGEN viruses, but not the ones generated by VCL32 and NGVCK. AVG Anti-Virus detected 27 viruses,

which are the G2, MPCGEN, and VCL32 viruses. The 10 NGVCK viruses were not detected by either scanner.

Figure 20 is a screen capture of the eTrust test result. As shown in the figure, the detection method used was signature. The G2 viruses were identified as the "Anarchy Family" while the MPCGEN viruses were correctly classified as the "PS-MPC Family". Avast antivirus named all MPCGEN virus infections as "PS/MPC-gen" and all G2 virus infections as "PS/G2-B".

Figure 20 Screen capture of the eTrust scanning result on the 37 virus executables.

Figure 21 is the AVG test result. Of the seven MPCGEN viruses, three were reported as "Could be infected PS-MPC" while the other four plus nine of the G2 viruses were

shown as unknown viruses. The scanner misclassified all VCL32 viruses as "Win32/Ngvck.W" while none of the NGVCK viruses was actually detected.

Figure 21 Test result for AVG Anti-Virus on the 37 virus executables.

NGVCK viruses were able to escape detection by the scanners we tested. However, as we have shown, both the similarity index approach and the hidden Markov model approach were able to identify them with high accuracy. We conclude that these two methods are very effective in dealing with NGVCK viruses.

6. CONCLUSION

Virus writers and anti-virus researchers generally agree that metamorphism is the way to generate undetectable viruses. Several virus writers have released virus creation kits and

claimed that they possess the ability to automatically produce morphed virus variants that look substantially different from one another.

To see how effective these code morphing engines are, and how much difference exists between variants of a given virus, we measured the similarity between virus variants generated by four virus generators downloaded from the Internet. Our results show that the effectiveness of these generators varies widely. While the best generator, Next Generation Virus Creation Kit (NGVCK), is able to create viruses that share only a few percent of similarity, the other generators produce viruses that are over 60% similar, on average. In addition, our similarity graphs show that some of these variant pairs have long segments of identical assembly opcodes at identical positions of the virus files. Compared to random utility files which have a similarity of about 35%, we see that some of the virus creation kits do not effectively morph the viral code.

Not only do NGVCK viruses show low similarity among themselves, they show even lower similarities when compared to viruses generated by other generators (from 0 to 5.5%). When compared to normal random files, the similarity scores are almost always zero, with only a few exceptions. We conclude that NGVCK viruses have the highest degree of metamorphism among the four virus families we tested. In addition, NGVCK viruses are very different from normal programs and viruses in other families.

To detect metamorphic virus variants, we experimented with hidden Markov models (HMMs) to capture the statistical properties of viruses in the same family. We generated 200 NGVCK viruses, trained 25 models and used the trained models to classify both viruses and random non-viral programs. Of the 25 models, 23 were able to identify all the normal programs by their scores alone. This means we can easily distinguish a NGVCK virus from a normal program.

70

The models also distinguished between VCL32 (Virus Creation Lab for Win32) viruses and other viruses not belonging to the NGVCK family. They assigned higher scores to VCL32 viruses, which were the only viruses we tested that have some similarities to the NGVCK family. Even so, seven of our models were able to perfectly distinguish the NGVCK viruses from the VCL32 viruses by scores. The other models produced different number of false positives and false negatives, depending on the threshold used in the classifying process. Using -4.5 as the threshold, 17 of the models achieved a 100% detection rate, with a false positive rate ranging from 0% to 7.7%.

If the variants of a metamorphic virus are sufficiently different that signature-based scanning cannot detect a newly morphed variant, the HMM approach provides a feasible solution. As with any statistical detection method, false predictions are possible. In our tests, false positives were all due to viruses from a different family than those in the training set, rather than normal non-viral programs. Therefore, we can view these false positives in a positive light, since the HMM detects additional viruses which have statistical properties similar to the viruses that the HMMs represent.

The number of states N of a model does not seem to have much impact on the performance of the HMM. We saw only small differences in the performance measures for models with N from 3 to 6. Since the time to train a model and the time to score a program increases with the number of states N, we may want to use a smaller N if time is crucial to the detection process. The trained models grouped the observed opcodes under the hidden states according to the probabilities that they were seen. This should help us infer features of the NGVCK viruses.

The fact that NGVCK viruses have assembly code structures that are different from normal programs and other viruses makes them distinguishable by our straight-forward similarity index alone. Our two tests that used similarity indices to classify 105 programs were both 100% accurate. This result illustrates that even though the NGVCK viruses show a high degree of metamorphism, it is still relatively easy to detect them since they are "too different" from normal programs. The similarity index approach is remarkably effective when the virus code structure is significantly different from normal non-viral code.

We scanned the viruses from the four families with three virus scanners. Viruses in the three families other than the NGVCK were detected by the three scanners. All NGVCK viruses escaped detection by these signature-based scanners. While the NGVCK viruses were not detected by the scanners we tested, we have shown that both the similarity index approach and the HMM approach are very effective in dealing with these viruses.

For viruses to avoid detection, they not only need a high degree of metamorphism, but also a degree of similarity to normal programs. None of the virus construction kits we tested satisfy both of these requirements. Three of the four virus generators fall short on metamorphism, while the one generator that is highly metamorphic lacks sufficient similarity to non-viral code. As a result, all these viruses are relatively easy to detect. An interesting open question is whether it is possible to satisfy both metamorphic and similarity conditions and thereby create a truly undetectable virus.

7. FUTURE WORK

We trained our models on disassembled virus executables. The disassembling process can take some time and the results depend on the quality of the disassembler. To speed up virus pre-processing and to eliminate the reliance on a particular disassembler, we could attempt to train the HMMs directly on the binary code of the viruses. Other machine learning techniques, such as data mining or neural networks, might also work directly on the binaries.

Training on raw executable byte sequences is more challenging as these byte sequences are longer and contain more irrelevant parts. We can train the models using only the code

segments and perhaps the data segments, excluding header and other kinds of identification information, since the behavior of a program is primarily determined by its code segments.

To more thoroughly evaluate the performance of the HMM approach, it would be useful to test on a larger set of virus variants and also test on different types of viruses. Ideally, we would like to find viruses that are similar to normal programs to a degree that the similarity index alone cannot distinguish the viruses from normal code. Only with such data can we evaluate the effectiveness of the HMM approach to detecting metamorphic viruses. However, it appears that no metamorphic kit available today is capable of producing such challenging viral code.

Appendix B: HMM training and testing results

Table B-1 Log likelihood per opcode (LLPO) of family viruses, non-family viruses and normal files with N = 3.

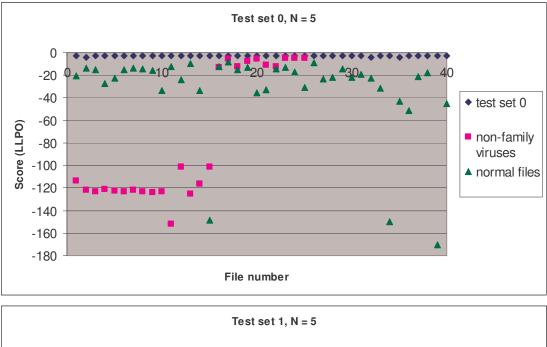

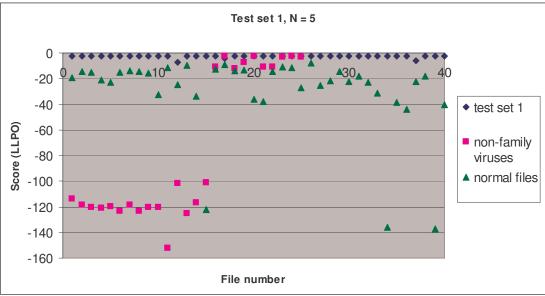

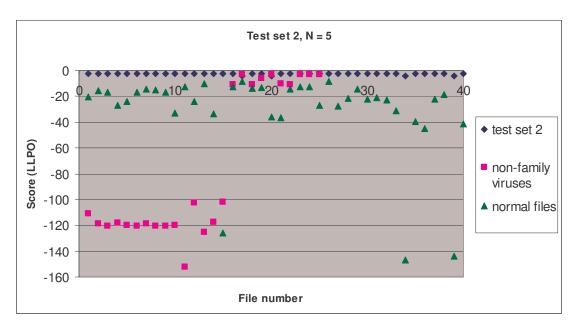

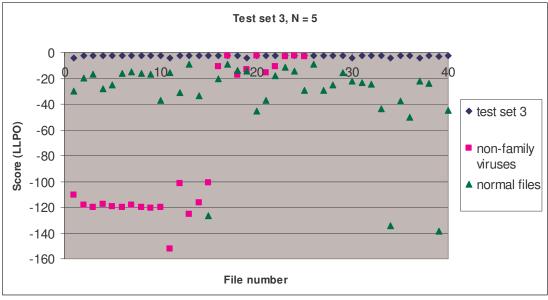

Table B-2 Log likelihood per opcode (LLPO) of family viruses, non-family viruses and normal files with N = 5.

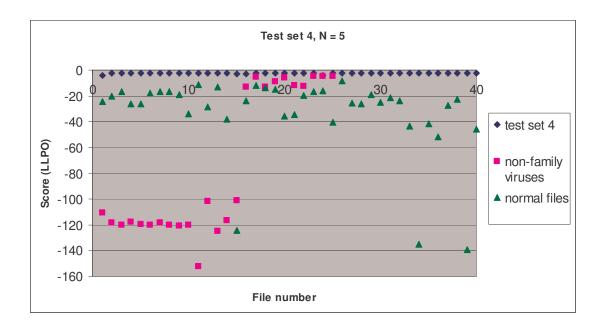

Table B-3 Raw LLPO scores of all 105 programs returned by the 25 HMMs. The scores are grouped according to the test set used by an HMM. For each test set, 5 models with N = 2 to 6 were tested.

Test set 0	N = 2	N = 3	N = 4	N = 5	N = 6	Test set 1	N = 2	N = 3	N = 4	N = 5	N = 6
